Abstract

The interiors of all living cells are highly crowded with macromolecules, which results in a considerable difference between the thermodynamics and kinetics of biological reactions in vivo from that in vitro. To begin to elucidate the principles of intermolecular dynamics in the crowded environment of cells, employing Brownian dynamics (BD) simulations, we examined possible mechanism(s) responsible for the great reduction in diffusion constants of macromolecules in vivo from that at infinite dilution. In an E. coli cytoplasm model comprised of 15 different macromolecule types at physiological concentrations, where macromolecules were represented by spheres with their Stokes radii, BD simulations were performed with and without hydrodynamic interactions (HI). Without HI, the calculated diffusion constant of green fluorescent protein (GFP) is much larger than experiment. On the other hand, when HI were considered, the in vivo experimental GFP diffusion constant is almost reproduced without adjustable parameters. In addition, HI give rise to significant, size independent intermolecular dynamic correlations. These results suggest that HI play an important role on macromolecular dynamics in vivo.

1. Introduction

One of the most characteristic features of the interiors of cells is the high total concentration of biological macromolecules. Typically, 20-40% of the cytoplasmic volume is occupied by proteins, nucleic acids and other macromolecules [1-3]. Under these conditions, although the molar concentration of each protein ranges from nM to μM, the distance between neighboring proteins is comparable to the size of the proteins. Therefore, simulating the crowded intracellular environment is crucial to understanding the nature of living systems.

Diffusion is one of the most important physical parameters that describe motions of molecules in a fluid. Recently, Elowitz et al. [4] and Konopka et al. [5] applied fluorescence recovery after photobleaching to measure the diffusion coefficient of green fluorescent protein (GFP) in the E. coli cytoplasm. Both groups reported that the diffusion coefficient of GFP in vivo is about 10 times less than that at infinite dilution in water. What is responsible for this reduction? In this study, as a necessary first step towards whole cell modeling, we performed Brownian dynamics (BD) simulations of the E. coli cytoplasm to address the
importance of hydrodynamic interactions on diffusion. While intermolecular HI play an important role in determining the dynamics of concentrated particles [6, 7], it has been neglected in the most simulations of biological macromolecules due to its long-range nature and high computational cost. Here, we apply Stokesian dynamics to simulate the diffusion of a polydisperse collection of macromolecules in crowded, heterogeneous intracellular 3D environments.

2. Methods

2.1. Hydrodynamic Interactions

The Rotne-Prager-Yamakawa (RPY) tensor is commonly used to take into account the HI in dynamic simulations of biomolecules because this tensor retains positive definiteness even when particles overlap [8-10]. Actually, the RPY tensor contains the two-body long-range or far-field contributions to particle mobility. However, in concentrated systems, e.g. the inside of cells, far-field many-body HI as well as near-field HI, so-called “lubrication forces”, play important roles in determining mobility (see Fig. 4 in Ref. [11]). In order to include not only the far-field HI but also the many-body and near-field HI in simulations, the Durlofsky-Brady-Bossis approach to “Stokesian dynamics” was used [6, 12]. Their approach can reproduce the properties of dense monodisperse suspensions whose volume fraction is up to 0.50 [13, 14]. Here, we briefly outline this method. For details, please refer to the original reference [12].

For $N$ particles system in a Newtonian fluid and in absence of an external shear flow, the hydrodynamic forces acting on particles, $F$, are related to the particle velocities, $U$, through the Stoke equation:

$$ F = R \cdot U, \quad (1) $$

where $R$ is the resistance matrix and is the inverse of the mobility matrix, $M$:

$$ R = M^{-1}. \quad (2) $$

When torque-angular velocity is not considered, the so-called “F version” in Ref. [12], $F$ and $U$ are $3N \times 1$ vectors and $R$ and $M$ are $3N \times 3N$ matrices. Then, the diffusion matrix of the system is simply given by

$$ D = k_B T M. \quad (3) $$

Here, $k_B$ is Boltzmann constant and $T$ is the temperature. The resistance tensor $R$, which contains both near-field lubrication effects and far-field many-body interactions, is calculated as

$$ R = (M^\infty)^{-1} + R_{2B}^\infty - R_{2B}^\infty. \quad (4) $$

The first term, $(M^\infty)^{-1}$, represents the contribution of many-body, far-field interactions. The second term, $R_{2B}$, represents the exact two-body HI, which includes both near-field and far-
field interactions. The third term $R_{2B}^{\infty}$ is the resistance tensor that represents two-body far-field interactions. The far-field part has already been included on $(M^{\infty})^{-1}$. Thus, in order not to count these interactions twice, we must subtract off the two-body interactions. This is the standard method to correct for the lubrication effects in the resistance tensor.

$M^{\infty}$ can be estimated by the Ewald summation of the RPY tensor developed by Beenakker for the case of periodic boundary conditions [15]. Due to the long range nature of HI (which decays as $1/r$, with $r$ the intermolecular distance between particles), use of the Ewald summation technique is necessary not only for accuracy but also for obtaining positive definite matrices in the calculation of the mobility tensor under periodic boundary conditions [14]. In addition, inverting $M^{\infty}$ corresponds to including many-body interactions [12]. $R_{2B}$ is calculated by the exact two-body solution of Jeffrey and Onishi [16]. $R_{2B}^{\infty}$ is obtained by simply inverting a two-body mobility matrix containing terms to the same order in $1/r$ as $M^{\infty}$.

When lubrication effects were added to the resistance tensor, the correction method developed by Cichocki et al. [17] is used to prevent a divergence of the translational self-diffusion coefficient for certain configurations. Collective motions are separated out from the standard lubrication correction as follows [17]:

\[
R = (M^{\infty})^{-1} + S_{2B} - S_{2B}^{\infty}, \quad (5)
\]

where

\[
S_{2B} = \sum_{\alpha} \sum_{\beta > \alpha} N \cdot N^T \cdot R_{2B}^{\infty} (\alpha, \beta) \cdot q, \quad (6)
\]

\[
S_{2B}^{\infty} = \sum_{\alpha} \sum_{\beta > \alpha} N \cdot N^T \cdot R_{2B}^{\infty} (\alpha, \beta) \cdot q. \quad (7)
\]

Here, $\alpha$ and $\beta$ represent indices of particles, and the matrix $q$ is given by

\[
q = \frac{1}{2} \begin{pmatrix}
I & -I \\
-I & I
\end{pmatrix} . \quad (8)
\]

This modified correction method was essential to prevent a divergence of the translational self-diffusion coefficient for our crowded and heterogeneous system.

2.2. Brownian Dynamics Algorithm

When HI are considered, the diffusion tensor macromolecule depends in principle on the configuration of the entire system and varies over time. We can write the propagation equation for such Brownian particles as
where $\mathbf{r}$ is the particle's position vector and $F^p$ is the deterministic conservative force acting on the particle. $G(\Delta t)$ is the random displacement due to Brownian motion, which has the following properties:

\[
\langle G(\Delta t) \rangle = 0, \quad \langle G(\Delta t) G(\Delta t) \rangle = 2k_B T M \Delta t.
\]  

(10)

In contrast to a BD algorithm with constant diffusion tensors, we need to evaluate the spatial gradient of the mobility tensor in the BD simulation with HI, in which the explicit computation of $\nabla \cdot \mathbf{M}$ is a $O(N^3)$ task. To avoid this expensive calculation, we used a method introduced by Banchio and Brady [18], which is based on Fixman's idea [19], the so-called “mid-point scheme”. In this method, Eqs. 9 and 10 are re-written as follows:

\[
\mathbf{r} = \mathbf{r}^0 + k_B T \left( \nabla \cdot \mathbf{M} \right) \Delta t + \mathbf{M} \cdot \left( F^p + F^B \right) \Delta t,  
\]  

(11)

\[
\langle F^B \rangle = 0, \quad \langle F^B(0) F^B(t) \rangle = 2k_B T \mathbf{R} / \Delta t. 
\]  

(12)

Here, $F^B$ is the Brownian force, obtained through the Cholesky decomposition [20]. The procedure for this mid-point algorithm is the following:

1. Compute the velocity $\mathbf{U}^0$ using an initial configuration $\mathbf{r}^0$

\[
\mathbf{U}^0 = \left( \mathbf{R}^0 \right)^{-1} \cdot \left( F^{p,0} + F^{B,0} \right).  
\]  

(13)

Here, superscript 0 represents the value evaluated at position $\mathbf{r}^0$.

2. Move the particles to intermediate positions $\mathbf{r}'$ by a small fraction of a time step, $\Delta t / m$

\[
\mathbf{r}' = \mathbf{r}^0 + \frac{\Delta t}{m} \mathbf{U}^0.  
\]  

(14)

In this study, an $m$ of 100 was used.

3. Calculate a new velocity $\mathbf{U}'$ at the intermediate positions using the forces evaluated at $\mathbf{r}^0$

\[
\mathbf{U}' = \left( \mathbf{R}' \right)^{-1} \cdot \left( F^{p,0} + F^{B,0} \right).  
\]  

(15)

4. Calculate the drift velocity, $\mathbf{U}_{\text{drift}}$,

\[
\mathbf{U}_{\text{drift}} = \frac{m}{2} \left( \mathbf{U}' - \mathbf{U}^0 \right).  
\]  

(16)
5. Finally, update the positions of the particles for time step $\Delta t$.

$$r = r^0 + \left( U^0 + U^{\text{drift}} \right) \Delta t. \quad (17)$$

For the simulations without HI, Ermak and McCammon algorithm described by Eqs. 9 and 10 was used [20, 21].

### 2.3. Simulation System

A simulation system having over 1,000 macromolecules consisting of 15 different kinds of proteins and tRNA was constructed in a 100 nm $\times$ 100 nm $\times$ 100 nm box based on the data reported by Ridgway et al [22] and the CyberCell database of the physical properties of *E. coli* [23], where each macromolecule was represented by an equivalent sphere with their Stokes radii (Table 1, Fig. 1). Stokes radii were estimated by using rigid-particle theory [21, 24]. The macromolecular concentration was set to 300 mg/ml, which is a reasonable estimate of the macromolecular concentration in *E. coli* (300–340 mg/ml) [3]. Volume occupancies calculated with the Stokes radii and radii of gyration of the macromolecules are 51% and 22%, respectively.

### 2.4. Repulsive Interaction Model

Repulsive interactions between intermolecular particles in BD simulations without HI were represented by a soft-sphere potential described by

$$V_{ss}(r_{ij}) = \begin{cases} 
{k_{ss}(r_{ij} - r_m)^2} & \text{if } r_{ij} \leq r_m \\
0 & \text{if } r_{ij} > r_m,
\end{cases} \quad (18)$$

where $r_{ij}$ is the distance between particles $i$ and $j$, and $k_{ss}$ is a force constant. $r_m$ is $r_c + \Delta_{ss}$, in which $r_c$ is sum of radii of particles $i$ and $j$, $a_i$ and $a_j$, and $\Delta_{ss}$ is an arbitrary parameter representing a buffer distance between particles. In this study, a $\Delta_{ss}$ of 2 Å and $k_{ss}$ of $5k_B T/\Delta_{ss}^2$ were used, which means $V_{ss} = 5k_B T$ at the distance $r_c$. In BD simulations with lubrication forces, we do not use any repulsive forces between particles, since the lubrication forces prevent particles from overlapping.

### 2.5. Simulation Conditions and Analysis

All simulations were performed at 298 K with periodic boundary conditions. For all simulation systems, ten different initial configurations for each system were randomly generated without significant overlaps to insure representative conformational sampling. For BD simulations of the repulsive model without HI, 30 $\mu$s simulations were performed with a time step of 0.5 ps. For simulations with HI, 12 $\mu$s simulations were performed with a time step of 2 ps. Trajectories for the first 5 $\mu$s of simulations were discarded for analysis. In calculating lubrication forces, particle pairs having $s < 4$ were evaluated every time step, where $s = 2r_{ij}/(a_i + a_j)$. On the other hand, since far-field HI are insensitive to small configuration changes, $M^\infty$ was computed every 500 steps.
In simulations that include HI, the short-time self diffusion coefficient for translational motion of particle type \(i\), \(D^S_i\), is defined by [11]

\[
D^S_i = \frac{1}{3N_i} \sum_{\alpha = 1}^{N_i} \text{tr}(D^{\alpha \alpha}). \tag{19}
\]

Here, \(N_i\) is the number of type \(i\) particles in the system and \(D^{\alpha \alpha}\) is the 3 \(\times\) 3 matrix of the self part of the diffusion tensor. The long-time self diffusion coefficient is defined as

\[
D^L = \lim_{t \to \infty} \frac{1}{6t} \langle \left| \mathbf{r}(t) - \mathbf{r}(0) \right|^2 \rangle. \tag{20}
\]

Finally, to analyze the correlations between particles in time and space, we calculate the normalized pair correlation function, \(C_{ij}\), given by

\[
C_{ij}(d_0, \tau) = \frac{\sum \left[(\Delta \mathbf{r}_i(\tau) \cdot \Delta \mathbf{r}_j(\tau)) \delta(d_0 - d_{ij})\right]}{\sqrt{\sum |\Delta \mathbf{r}_i(\tau)\delta(d_0 - d_{ij})|^2} \sqrt{\sum |\Delta \mathbf{r}_j(\tau)\delta(d_0 - d_{ij})|^2}}, \tag{21}
\]

where \(d_0\) is a specified the surface distance between particles \(i\) and \(j\), and \(\tau\) is the time interval. \(\delta(d_0 - d_{ij})\) is the Dirac delta function. \(d_{ij}\) is the surface distance between particles \(i\) and \(j\) at time \(t\) given by

\[
d_{ij} = |\mathbf{r}_i(t) - \mathbf{r}_j(t)| - a_i - a_j. \tag{22}
\]

The summation in Eq. 21 is over all time points \(t\) and all independent simulations.

### 3. Results

#### 3.1. Effect of Excluded Volume and Hydrodynamic Interactions on Diffusion

We performed BD simulations with and without HI to evaluate the effects of HI on diffusion in crowded environments. In addition to the RPY [25, 26] interaction tensor, (widely used in biomolecular simulations to incorporate the long-range effects of HI), we also account for the lubrication forces that play a crucial role in the short-range interactions that are especially important in dense systems [6, 11].

Fig. 2 shows \(D^S_i/D_0\) and \(D^L_i/D_0\) values at three different concentrations as a function of Stokes radius, where \(D_0\) is the diffusion coefficient in infinite dilution. \(D^S_i/D_0\) obtained from the BD simulations of sphere systems with just steric repulsions are also similar. Similar to the simulations without HI, \(D^S_i/D_0\) and \(D^L_i/D_0\) decrease with increasing radius. For \(D^S_i\), HI greatly reduces the diffusion constants of all particles; in contrast, \(D^S_i\) is always equal to \(D_0\) when HI are ignored; the reduction in short-time diffusion coefficient is a purely hydrodynamic property; \(D^S_i\) equals \(D_0\) when HI are absent [13].

In in vivo experiments, \(D^S_i/D_0\) of GFP is 0.06–0.09 [4, 5] (see Fig. 2). On the other hand, \(D^L_i/D_0\) value of GFP in the simulated equivalent sphere system without HI is 0.31; this is more than 3 times larger than experiment. This result indicates that although excluded...
volume effects reduce macromolecular diffusion in intracellular environments, they cannot explain the factor of ~10-16 reduction observed in vivo. However, when HI are considered, BD simulations give \( D/L/D_0 = 0.14 \) for at 300 mg/ml, which is close to the observed experimental values (Fig. 2). Because the concentration of macromolecules in the E. coli cytoplasm is estimated to be in range of 300–340 mg/ml [3], the concentration of 300 mg/ml used in this study is a lower limit of physiological conditions. Therefore, diffusivity of GFP obtained from the simulation at higher concentrations get even closer to experiment. These results indicate that steric crowding and HI are two major factors responsible for the reduction in diffusion of macromolecules in intracellular environments. Indeed, without any other assumptions, these two effects well reproduce the experimentally observed diffusion constant of GFP in vivo.

### 3.2. Large-distance and Long Time Intermolecular Correlations

Next, the dynamical correlations in space and time between macromolecules were examined. Such effects are expected to be present when HI are included. To analyze the correlation between particles, we calculated a normalized pair correlation function, \( C_{ij} \). \( C_{ij} \) ranges from −1 to 1. When two particles are positively correlated, \( C_{ij} > 0 \), and when they are negatively correlated, \( C_{ij} < 0 \).

Representative \( C_{ij} \) of large and small particle pairs up to 100 ns in time and 10 Å in space for the sphere system with and without HI as well as with the non-specific attractive interaction model are shown in Fig. 3. In the model without HI, where \( D/L \sim 3 \) times larger than in the HI model, (Fig 3 top) \( C_{ij} < 0.1 \) even at short times (< 30 ns) for both pairs. In contrast, for both pairs of molecules, a significant positive intermolecular dynamic correlation for the simulation with HI is evident, though these are on average weak, \( C_{ij} < 0.3 \). These results clearly show that HI give rise to quite long distance and time dynamical correlations between particles of all sizes even in the high crowded environment.

### 4. Discussion

The goal of this study is to evaluate the role of HI in the reduction of macromolecular diffusion in intracellular environments. To ascertain the importance of HI, we performed BD simulations that take into account not only far-field HI but also near-field lubrication effects in three dimensions. The key finding of this work is that the two factors, excluded volume effects and HI, are sufficient to explain the large reduction in diffusion of macromolecules observed in vivo. Indeed, the diffusion constant of GFP in vivo can be almost quantitatively predicted by the inclusion of HI without any adjustable parameters or other ad hoc assumptions.

A number of other factors can also affect intracellular diffusion: 1) Electrostatic interactions between molecules. In principle, electrostatic interactions are long-ranged. However, the salt concentration inside cells is ~150 mM, so that they are well screened with a Debye length of ~8 Å. McGuffee and Elcock recently simulated a bacterial cytoplasm model where electrostatic interactions were treated by using Poisson-Boltzmann equations [27]. However, the diffusion coefficient of GFP is just slightly smaller than that obtained without electrostatic interactions; both values were 3–4 times larger than experiment. Heterogeneous
charge distributions on molecular surface, like in real biomolecules, may affect macromolecular motions. However, since electrostatic interactions are highly screened due to the short Debye length found in physiological conditions, we believe that our conclusions would not qualitatively change. 2) Viscosity of the cytoplasm. In our simulations, the viscosity of the cytoplasm equals the value in water. The in vivo cytoplasm viscosity has been measured and is not significantly larger than bulk water, i.e. it is less than 2 cP [2, 22, 28]. 3) GFP dimerization. It is well known that GFP tends to dimerize in solutions of low (<100 mM) ionic strength [29]. All of these physical factors will decrease macromolecular diffusivity in vivo. However, based on other work [27] and our results, which show that the reduction in diffusion of GFP in the simulation with HI is close to experiment, we expect the contribution of these three factors to be small.

Our results have demonstrated the likely importance of HI in macromolecular diffusion in vivo. However, there are a few possible limitations: First, the properties of a fluid on the nanometer scale are different from the bulk [30-32]. HI determined by solving Stokes equations may not fully describe the molecular situation. In order to fully validate the continuum limit assumption, molecular dynamics simulations with explicit solvent models would be necessary. Second, HI were considered only for the equivalent sphere system where the detailed molecular shape is ignored. Without HI, we demonstrated that this is a very good approximation [21, 24], but we have not explicitly shown this for the system with HI. Recently, an analytical formula that estimates the crossover time from anisotropic to isotropic diffusion of an arbitrarily shaped object in three dimensions using its $6N \times 6N$ diffusion tensor matrix was introduced [33]. The longest crossover time of molecule in our simulation system estimated by using this formula is 1.7 μs for the ribosome. Therefore, the effect of shape and diffusion anisotropy on the analysis of long-time translational diffusion is expected to be small.

Genome-sequencing has provided a detailed “parts list” for life [34]. Recently, the proteome wide prediction of protein structure and function has also become practical [34-40]. The next frontier in biophysics is to integrate this information and construct in silico cells that not only can describe the behavior of living systems in terms of individual biomolecules but which also can elucidate new biological principles describing their collective behavior. Until now, little attention has been paid to the biophysical properties of the crowded, heterogeneous environments found in cells, which have a great impact on the biological processes taking place. Therefore, modeling these crowding effects is an important first step towards whole cell simulation. The simulation method developed in this study could be a good tool to analyze the in vivo thermodynamics and kinetics of macromolecular dynamics.

† Stokes radii were calculated by $6\pi\eta a = k_B T/D_0$, where $\eta$ is the viscosity of water, $D_0$ is the translational diffusion coefficient in dilute solution estimated by the rigid-particle theory [21, 24], and $a$ is the Stokes radius.

‡ The diffusion constants are at 298 K.
